Basic Principles of Pulse Echo

- Short pulses transmitted to patient and then reflected back
- High frequency used above human hearing so that it propagates as a narrow beam, thus return can be assumed to come from object along scan line

Acoustic Pulse – Echo concept
- Transducer converts:
  1. Electricity -> Sound – transmits through tissue
  2. Sound -> Electricity to produce echo

Pulse - Echo
- Electric pulse is applied to piezoelectrical crystal in probe, thus leading to change in shape of crystal
- This leads to compression of tissue under probe (acoustic pressure)
- Tissue compression and rarefaction (decompression) will move away from the crystal – speed of 1540m/s in soft tissue – acoustic wave
- Rate of compression/rarefaction determines frequency of wave
- Interaction of pulse with nonhomogenous tissue will lead to scatter and reflection (back to the crystal)
- Once wave returns to crystal, crystal again deforms, which generates an electric field. Amplitude depends on amount of compression of crystal

Frequency (f)
- Hertz (f) = 1 cycle per second
- We hear at frequencies between 20Hz and 20kHz (20-20,000 cycles per second)
- Echo transducers use frequencies between 2 MHz and up to 12 MHz (2,000,000-12,000,000 cycles per second)

Frequency
- Shorter time between peaks (more cycles) = higher frequency
- Pulse repetition frequency (prf) = rate at which the transmit/receive process repeats, can be several hundred, even thousands of pulses per second
- Shallower scans take shorter time for signal to return, thus allowing higher prf
Pulse Repetition Frequency
- Transducer transmits and receives
- Occurs at a certain rate (known as pulse repetition frequency, PRF)
- Several hundred or thousand pulses per second, depending on depth
- Neonates have shallower targets that allow for higher PRF
- Processing of information back to the transducer allows creation of image

Wavelength
- Distance traveled by sound in 1 cycle
- Inversely proportional to frequency such that shorter wavelength allows for higher frequency
- Smaller wavelength = higher resolution though less penetration
- Thus in neonates, 12MHz probe will provide more higher resolution but less depth than a 5MHz probe

Velocity
- Sound propagates through soft tissues at an average speed of 1540m/s
- Speed depends on compressibility and density of material
- Fastest through muscle
- Slow through fat

Interaction of ultrasound waves with the body
- Reflection
- Scattering
- Refraction
- Attenuation

Reflection
- Associated with larger objects (greater surface than ultrasound beam) such as valves or walls
- Occurs when the interfaces have different acoustic impedances that cause reflection of the sound wave
- Large echo/reflection if beam perpendicular to source
- Can have dropout of signal if beam parallel, eg in 4 chamber apical view when atrial septum is in line with the beam and can have dropout
Scatter

- Responsible for most of the echo images
- Occurs at smaller non-homogenous structures, such as walls of cells, capillaries, etc and sends weak echoes in many directions
- Important for differentiating between tissues (i.e. pericardium from myocardium)

Refraction

- Change of sound direction moving from one material of varying impedance to another
- Deflection/bending of the wave due to different velocities of acoustics between two materials

Attenuation

- As beam extends further from the probe, the amplitude decreases due to attenuation
- Likely related to conversion of energy to heat
- Thus, signal becomes darker and less resolution
- Varies on medium – air has high attenuation compared with blood or fluid
- Higher frequency has faster attenuation than low frequency transducer

Various modes of Pulse-Echo scanning

1. A-mode scan
2. M-mode scan
3. B-mode scan

A Mode scan

- Simplest form of scanning
- No longer used
- Transducer held in place and amplitude determined (time taken for sound to return to probe)

M-mode Scan

- Single line interrogation
- Amplitude expressed as brightness
- Stationary targets are straight lines, while moving tissues draw out waves
B Mode (2D) Imaging

- Most commonly displayed
- Cross sectional area of the body by 2D
- Need high frame rates for good temporal resolution
  - Ability to detect moving objects in the field of view, i.e. faster than the heart rate

Probes

- Sector/Phase array Probes
  - Large depth of field with small footprint; e.g. used for chest as able to extend beam between ribs

- Linear Probe
  - Wider field of view close to surface, high resolution, good for line placement

- Curvilinear
  - Deep penetration and wide field, low frequency, good for abdominal structures

- Radial
  - Extension of sector scanning, used for viewing inside the body
Types of Resolution

1. Spatial Resolution
   • Axial Resolution
   • Lateral Resolution
2. Temporal Resolution

Axial Resolution
- Ability to distinguish between 2 objects close together along the scan line
- Affected by frequency
  • Higher frequency, thus shorter wavelength = better axial resolution

Lateral Resolution
- Ability to distinguish between 2 objects close together perpendicular to the scan line

Temporal Resolution
- Ability to detect movement of object along its trajectory in its true course – defined as frame rate
- Can improve temporal resolution by decreasing sector width so less area to cover
- Decrease the depth of the image to decrease the pulse repetition frequency

Remember...
- Higher frequency probe = better resolution but less penetration
- Lower frequency probe = better penetration but worse resolution

Image Construction from Pulse-Echo concept
- Signal returning from body to transducer is divided into pixels
- Each pixel is assigned a number based on amplitude, ranging from black to white with ranges of grey in between
  • Bright pixels = high amplitude (bone)
  • Dark pixels = low amplitude (e.g. blood)
Ultrasound Safety

- **Heating**
  - Absorption within the tissue
  - Generated with non-scanning modes (e.g. PW doppler), deep focus, narrow zoom box
  - Temp rise up 6°C possible with PW doppler on bone and 2.5°C on soft tissue

- **Cavitation**
  - Bubbles can form in liquid with pressure variations
  - If negative pressure deep or long enough, may grow bubble and collapse, releasing energy
  - Risk with low frequency probe, long pulse length high pulse repetition
